Abstract—Mountain river torrents and snow avalanches generate human and material damages with dramatic consequences. Knowledge about natural phenomena is often lacking and expertise is required for decision and risk management purposes using multi-disciplinary quantitative or qualitative approaches. Expertise is considered as a decision process based on imperfect information coming from more or less reliable and conflicting sources. A methodology mixing the Analytic Hierarchy Process (AHP), a multi-criteria aid-decision method, and information fusion using Belief Function Theory is described. Fuzzy Sets and Possibilities theories allow to transform quantitative and qualitative criteria into a common frame of discernment for decision in *Dempster-Shafer Theory (DST)* and *Dezert-Smarandache Theory (DSmT)* contexts. Main issues consist in basic belief assignments elicitation, conflict identification and management, fusion rule choices, results validation but also in specific needs to make a difference between importance and reliability and uncertainty in the fusion process.

Keywords: natural hazards, expertise, decision-making, multi-criteria decision making, Analytic Hierarchy Process (AHP), DST, DSmT.

I. INTRODUCTION

Mountain river torrents and snow avalanches generate human and material damages with dramatic consequences. In the natural hazards context, risk is assessed as a combination of hazard and vulnerability levels. This formulation can be considered as equivalent to a combination of frequency and gravity which is more currently used in industrial context (figure 1).

Figure 1. Equations of risk in natural hazards and industrial contexts.

Expertise is always required to define the types of possible phenomena, to assess the hazard and risk levels and to propose prevention measures. Expert judgements depend on quality

and uncertainty of the available information that may result from measures, historical analysis, testimonies but also subjective, possibly conflicting, assessments done by the experts themselves. As an example, the definition of risks zones is often based on the extrapolation of historical information known on particular points using morphology based analysis (figure 2).

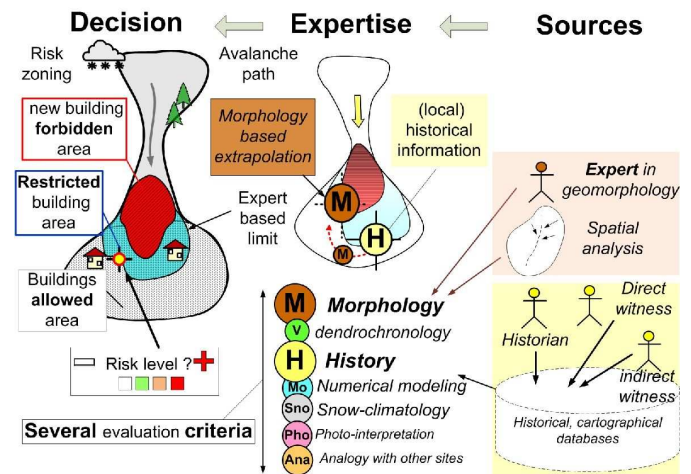

Figure 2. Information, expertise and decision in risk zoning applications.

At the end, phenomenon scenarios and decisions may very well rely on very uncertain information without being able to really know what was completely true, imprecise, conflicting or simply unknown in the hypotheses leading to these results. In that context, our essential hypothesis consists in considering expertise as a decision process based on imperfect information related to multiple criteria and coming from more or less reliable and conflicting sources.

This paper proposes a methodology able to help decision based on imperfect information. In section II, we briefly introduce the principles of multi-criteria decision analysis (MCDA) focusing on the AHP developed by T. Saaty (section II-A). The section II-B analyzes the existing methods using both MCDA methods and theories for uncertainty management. In section III, we present the different steps of a new methodology applying to a multi-criteria deci-

sion problem based on imperfect information resulting from more or less reliable sources. Conclusions and perspectives are given in section IV.

II. METHODS FOR MULTI-CRITERIA DECISION ANALYSIS AND IMPERFECT INFORMATION

Information and decision are closely linked and different methods exist to take a decision on the basis of imperfect information. From one hand, main principles of multi-criteria decision analysis and existing theories to manage imperfect information are over-viewed. From the other hand, we then briefly analyze the characteristics and lacks of existing methods methods using both *MCDA* methods and theories for uncertainty management.

A. The Analytic Hierarchy Process

Multi-criteria decision analysis aims to choose, sort or rank alternatives or solutions according to criteria involved in the decision-making process. Main steps of a multi-criteria analysis consist in identifying decision purposes, defining criteria, eliciting preferences between criteria, evaluating alternatives or solutions and analyzing sensitivity with regard to weights, thresholds, ... Total aggregation methods such as the Multi-Attribute Utility Theory (M.A.U.T.) [11], [13] synthesizes in a unique value the partial utility related to each criterion and chosen by the decision maker. Each partial utility function transforms any quantitative evaluation of criterion into an utility value. The additive method is the simplest method to aggregate those utilities (figure 3).

Figure 3. Multi-criteria decision method based on a total aggregation principle.

The Analytic Hierarchy Process (*AHP*) [12], [19], [20] is a single synthesizing criterion approach. This method is worldwide used in almost all applications related with decision-making [27]. *AHP* is a special case of complete aggregation method based on an additive preference aggregation and can be considered as an approximation of multi-attribute preference models [11]. Its principle is to arrange the factors considered

as important for a decision in a hierarchic structure descending from an overall goal to criteria, sub-criteria and finally alternatives in successive levels. It is based on three basic steps: decomposition of the problem, comparative judgments and hierarchic composition or synthesis of priorities (figure 4).

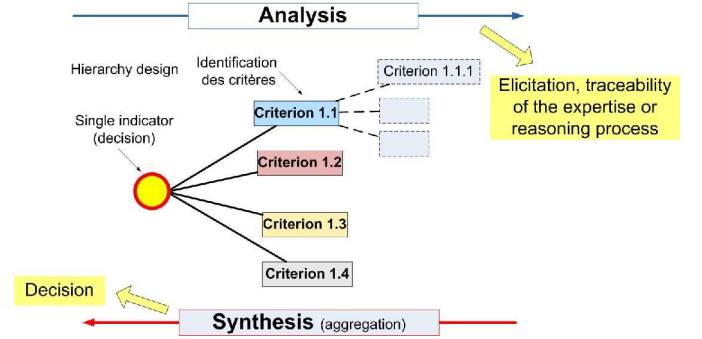

Figure 4. Principles of the analytic hierarchy process.

At each level of the hierarchy, a preference matrix is built up through pairwise comparisons using a semantic and ratio scale to assess the decision maker preferences between the criteria of the considered level. Through the *AHP* pairwise comparison process, weights and priorities are derived from a set of judgments that can be expressed either verbally, numerically or graphically. The original *AHP* process uses an additive preference aggregation and compares the solutions from one to each other in a so-called "Criterion-alternative approach". This implies to make pairwise comparisons between all the solutions or alternatives in order to obtain preferences levels between these alternatives. When dealing with great amount of data, this becomes quickly quite difficult. An other approach so-called "Criterion-index (or estimator)-alternative" is used in our developments (figure 5). Instead of comparing all the alternatives, the decision analyst evaluates, for each alternative, criterion according pre-existing classes. Each evaluation class corresponds to an increasing or decreasing level of satisfaction of a given criterion involved in the decision making. For example, the criterion *human vulnerability* exposed to natural hazards can be assessed according to three classes based on a number of existing and exposed buildings (figure 7). These classes code some kind of ordinal levels corresponding to a low, medium or strong contribution (or satisfaction) to (or of) the criterion. In that way, the *AHP* method, despite the known issues of complete aggregation methods, fits quite well to decision ranking problems where the alternatives are not all known.

B. Making a decision on the basis of imperfect information

Several theories have been proposed to handle different kinds of imperfect information: *Fuzzy Sets Theory* for vague information [29], *Possibility Theory* for uncertain and imprecise information [9], [30] and *Belief Function Theory* that allows to consider uncertain, imprecise and conflicting information. In addition to original *Dempster-Shafer* theory

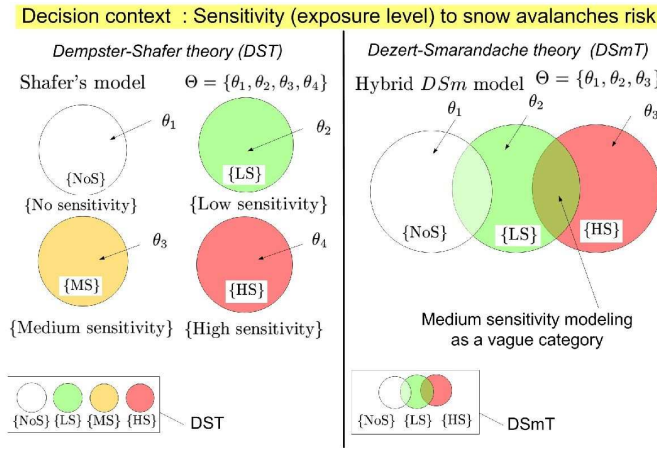

Figure 8. Two frames of discernment according to *DST* or *DSmT* frameworks.

A represents the proposition " $x \in [8, 15]$ ". $N(A) = 0.75$ represents the certainty level (confidence) in the proposition " $x \in [8, 15]$ ". $N(A)$ can be viewed as a lowest probability for A and $\Pi(A)$ as an upper probability for A (figure 9).

Figure 9. Using possibility distribution for imprecise criteria evaluation.

Any interval of the possibility distribution can be transformed into basic belief assignment (figure 10) according to relations between possibility and belief function theories [1], [2], [10].

Figure 10. Possibility distribution for evaluation are transformed into masses.

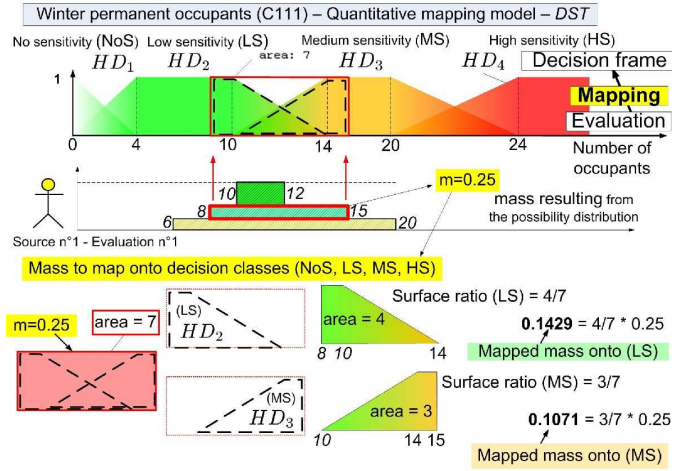

Figure 11. Mapping is based on surface ratios.

C. Mapping models: a link from evaluation to decision

A mapping model is a set of fuzzy intervals $L - R$ linking a criterion evaluation and the decision classes: it plays more or less the same role than the utility function in a total aggregation based multi-criteria decision method. For each evaluation of a criterion by one source, each interval of the possibility distribution ($I_{(s, int_j)}$) is mapped to the common frame of discernment of decision according to surface ratios (figures 11, 12). At the end of the mapping process, all the criteria evaluations provided by each source are transformed in basic belief assignments (bba's) according the common frame of discernment of decision: these bba's are then fused in a two-step process.

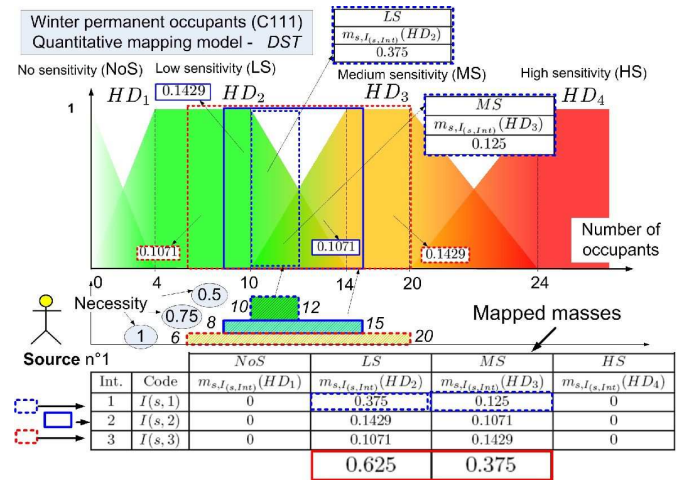

Figure 12. Results of mapping of the evaluation of source n°1 for criterion C_{111} .

D. Two steps of fusion

After the mapping step, the *ER - MCDA* process is based on two successive fusion levels (figure 13). The first step consists in the fusion of bba's corresponding, for each

criterion, to the different evaluations provided by different sources.

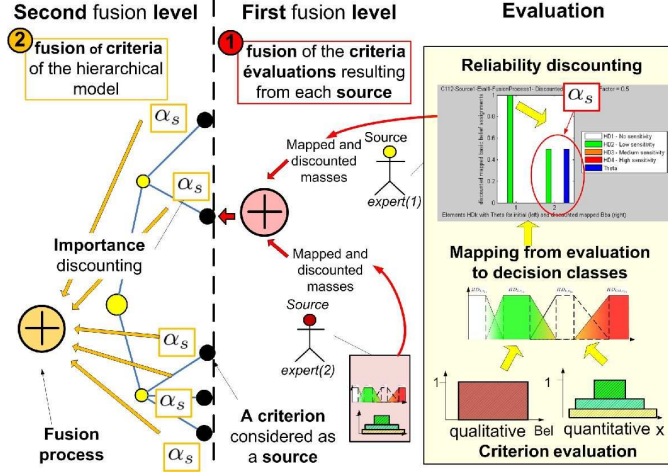

Figure 13. The fusion levels of the *ER-MCDA* process.

Reliability of each source is assessed using the classical discounting factor (α_s) proposed in the *DST* or *DSmT* frameworks. Then, fusion of this discounted bba's is done using different fusion rules. The *PCR6* rule [6], [7], [15] is recommended to prevent aberrant decisions in case of highly conflicting evaluations of a criterion (figure 14).

| Frame of discernment - <i>DST</i> - $\Theta = \{NoS, LS, MS, HS\}$ | | | | | |
|--|--------------|--------------|--------------|--------------|----------------|
| | NoS | LS | MS | HS | Θ |

| $m_{(C_{111})} = m'_1 \oplus m'_2$ | 0 | 0 | 0.1784 | 0.6229 | 0.0487 |
| $m_{(C_{111})}$ | 0.2335 | 0 | 0.0937 | 0.4834 | 0.0394 |

Figure 14. Examples of fusion results.

The second step consists in the fusion of the bba's corresponding to each criterion and resulting from the first step of fusion (figure 13). In this second step, each criterion is considered as a source which is discounted according its importance in the decision process as proposed by [3] (figure 15).

Results of fusion have to be interpreted to decide which is the sensitivity level that will be chosen (*NoS*, *LS*, *MS* or *HS*) according either to the maximum of basic belief assignments, credibility (pessimistic decision), plausibility (optimistic decision) or pignistic probability (compromise). The

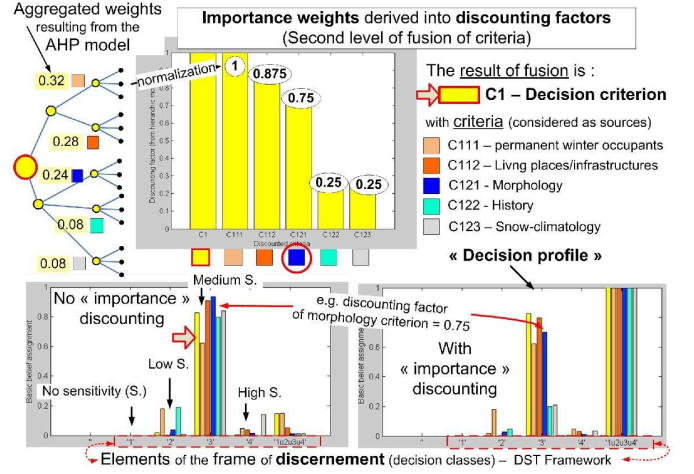

Figure 15. Importance discounting factors resulting from hierarchical multi-criteria model.

ER-MCDA methodology produces a comparative decision profile in which decision classes (elements of the frame of discernment) can be compared one to each other using *DST* or *DSmT* to fit in the best possible way to their nature (figure 16).

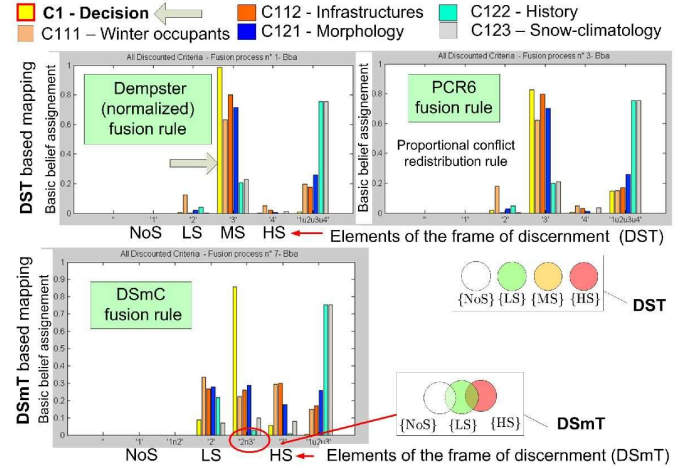

Figure 16. Comparison of fusion rules.

IV. CONCLUSION-DISCUSSION

The *ER-MCDA* methodology allows to make a decision based on multiple and more or less important criteria on which more or less reliable sources provide imperfect and uncertain evaluations. A simplified decision sorting problem based on a snow-avalanche risk management problem shows how the use of multi-criteria decision analysis principles and information fusion can be used to characterize and take information quality or imperfection into account for decision purposes. In regard with its aggregation principles and possible "rank reversals", *AHP* is as much criticized than it is widely used [14]. Anyway, it remains an easy understandable method that can be

simply connected to fusion process frameworks. The Analytic Hierarchy Process (*AHP*) elicits the criteria used for decision and is used as a conceptual framework. The *ER – MCDA* methodology contributes to improve traceability and quality description of the expertise process through clearly dissociated steps corresponding respectively to evaluation, mapping and fusion based decision making. *DSmT* proposes more valuable modeling principles for vague, imprecise and uncertain information and conflict management. Advanced fusion rules such as partial conflicting rules (*PCR*) cope with conflict in a more efficient way than the classical Dempster's rule used in the *DST* framework.

Sensitivity analysis must still be applied to the *ER – MCDA* methodology in order to explore the effects of fusion orders, mapping models ... changes. Using the classical discounting factor to consider both reliability and uncertainty at the first fusion step and importance at the second step of fusion is not satisfactory. A new discounting process must be proposed in this case [8], [25], [26].

From an operational point of view, an important application field consists in extending this methodology to spatial applications and specially to hazard and risk zoning maps.

ACKNOWLEDGEMENTS

This work would not have been possible without the help of Arnaud Martin who provided us the fusion routines that were used to implement our calculation framework [16].
